Abstract— Brain Tumors remain a serious concern in medical imaging, and thus, there is a need for trustworthy analytical tools to facilitate correct clinical decision-making. Although recent advances in deep learning have improved the performance of tumor segmentation and classification, many models lack the ability to assess the stability of predictions against minimal, anatomically valid perturbations. This paper presents Brainiac, a stability-conscious MRI-based framework for brain tumor analysis that combines transformer-based segmentation, counterfactual sensitivity analysis, and risk stratification. A Swin-UNETR model is employed for three-dimensional tumor segmentation, from which radiomic features and transformer attention entropy are derived. Tumor-conditioned counterfactuals are produced to calculate a Counterfactual Sensitivity Score (CSS), which is defined as the minimum perturbation required to change the model's prediction, and this score is used as a quantitative feature for risk classification. The experimental results on public brain MRI datasets show that the combination of CSS features with radiomic and attention-based features improves risk stratification performance compared to appearance-based models. The proposed framework provides interpretable and stability-conscious decision support for accurate brain tumor analysis.

Index Terms— Brain tumors, Magnetic resonance imaging, Transformer networks, Counterfactual explanations, Risk stratification, Explainable artificial intelligence

I. INTRODUCTION

Analysis of brain tumors still represents a significant task in the field of neuro-oncology, requiring accurate imaging analysis to enable informed decision-making. Magnetic resonance imaging (MRI) continues to be fundamental in the evaluation of tumors, with publicly accessible benchmarks such as the Brain Tumor Segmentation (BraTS) competition driving the creation of automated analysis tools [1]. Recent advances in deep learning techniques, including convolutional and hybrid architectures, have demonstrated their effectiveness on datasets of brain tumor images [2], [3]. Lately, transformer architectures like Swin-UNETR have shown to have improved overall contextual insight in volumetric MRI, reaching leading performance in three-dimensional tumor segmentation assignments [4].

Explainable artificial intelligence (XAI) methods, such as gradient-based attribution and counterfactual explanations, have been incorporated to enhance interpretability in medical imaging applications [5]–[7]. Nevertheless, these methods are generally used as visualization aids and are not integrated as quantitative indicators in predictive models. In high-stakes applications, predictive performance is no longer adequate, as visually similar tumors can have vastly different levels of decision stability. Although uncertainty estimation techniques provide probabilistic confidence indicators [8], [9], they fail to provide direct estimates of the minimal anatomically plausible perturbation necessary to traverse a model's decision boundary. At the same time, uncertainty estimation techniques have been proposed to provide model confidence estimates in medical imaging applications, including Bayesian approximations and test-time augmentation methods [8], [9]. Although these techniques provide probabilistic estimates of predictive performance, they fail to provide direct estimates of the minimal anatomically plausible perturbation necessary to traverse a model's decision boundary. As a result, visually similar tumors can have vastly different levels of decision stability that are not revealed by standard uncertainty estimates. To this end, this paper proposes Brainiac, a stability-aware MRI brain tumor analysis system that incorporates transformer-based segmentation, attention-driven feature extraction, and counterfactual-guided risk stratification. A Swin-UNETR backbone architecture is used for three-dimensional tumor segmentation, from which radiomic features and transformer attention entropy are derived to estimate tumor morphology and contextual uncertainty.

Tumor-constrained counterfactual samples are created to compute a Counterfactual Sensitivity Score (CSS), which is formally defined as the "minimal perturbation required to change the prediction." Unlike existing approaches that leverage counterfactuals exclusively for explanation, CSS is

incorporated as a quantitative feature into a downstream classifier to distinguish between patients with low, medium, and high risk levels based on prediction stability. The framework also provides dual-modal explanations through integrated gradients and counterfactual MRI visualizations, allowing for both spatial and causal analyses of prediction outputs. Experiments conducted on publicly available brain MRI datasets show that incorporating CSS with radiomic and attention-based features improves risk stratification performance over appearance-based baselines. Through the strategic incorporation of counterfactual explanations as learning signals, Brainiac provides a principled framework for stability-conscious modeling to support robust and interpretable brain tumor analysis.

II. LITERATURE SURVEY

This section reviews the latest advances in transformer-based brain tumor segmentation, explainable artificial intelligence (XAI), counterfactual learning, and uncertainty estimation in medical imaging, as per the proposed Brainiac framework. It integrates existing work on MRI-based segmentation, radiomic feature modeling, uncertainty estimation using attention, counterfactual learning with tumor constraints, and risk stratification with stability. This review places the Brainiac framework in the context of the literature and highlights its emphasis on counterfactual sensitivity as a measure of decision stability.

A. Introduction

Analysis of brain tumors in magnetic resonance imaging (MRI) has been greatly aided by recent developments in deep learning, where transformer models have improved the performance of volumetric segmentation in publicly available benchmarks such as BraTS [1], [2]. However, most existing models are primarily concerned with the accuracy of segmentation or classification and provide explanations only through post-hoc visualization. Recent works have proposed the use of counterfactual explanations and uncertainty estimation to improve the interpretability and confidence estimation of models [3]–[5]; however, such methods rarely provide a quantitative measure of prediction stability under anatomically valid perturbations or incorporate such knowledge into risk modeling. This scenario highlights the need for Brainiac, which translates tumor-constrained counterfactual sensitivity and transformer attention entropy into a feature for stability-aware risk stratification.

B. Transformer-Based Brain Tumor Segmentation

The state of automated segmentation of brain tumors has evolved from conventional convolutional neural networks (CNNs) to hybrid and transformer-based models. Although the early CNN-based models performed well on standard benchmarks like BraTS, they were limited in their ability to capture long-range spatial dependencies, which are characteristic of volumetric MRI images [1], [2]. Swin-UNETR is a significant step in this direction, which integrates shifted window transformers into a U-Net encoder - decoder structure [4]. This model has shown superior performance on three-dimensional brain tumor segmentation tasks, improving upon boundary definition and overall tumor region stability. Although these models are capable of producing accurate segmentation results, they are primarily designed to optimize pixel-level segmentation accuracy metrics and do not focus on the reliability or stability of predictive outcomes.

C. Radiomics and Feature-Based Brain Tumor Modeling

Radiomic analysis has been widely explored for its applications in tumor morphology, texture, and intensity pattern analysis in magnetic resonance imaging (MRI) [5]. Radiomic features, such as tumor volume, shape complexity, and texture entropy, have been shown to be correlated with tumor heterogeneity and prognosis [6]. More recent studies have combined radiomics with deep learning features to improve classification and predictive modeling accuracy [7].

However, radiomic analysis by itself is prone to variations in imaging and segmentation quality and does not account for model-internal uncertainty or decision robustness. This means that radiomics-based models could potentially fail to distinguish between tumors that look similar but have differing levels of prediction stability.The need to combine radiomics with model-internal uncertainty and stability measures arises from the above-mentioned challenges. In the proposed Brainiac framework, radiomic features are combined with transformer attention entropy and counterfactual sensitivity to provide a comprehensive representation of tumor morphology, contextual uncertainty, and decision robustness.

D. Explainable Artificial Intelligence in Brain Tumor Analysis

To improve the transparency and trustworthiness of medical image models, explainable artificial intelligence (XAI) approaches have been introduced. Gradient-based attribution techniques, such as the Integrated Gradients algorithm, have been used to provide spatial explanations of image models by attributing image regions that are most responsible for the model's prediction [8]. More recently, counterfactual explanations have been proposed as a new XAI technique to provide a causal "what-if" explanation by generating a minimally different input that causes a difference in the model's output [9]. For brain MRI images, tumor-aware counterfactual techniques such as TACE have been proposed to limit the perturbations to the tumor area, which improves anatomical correctness and explanation validity [10]. Although these techniques improve interpretability, most XAI techniques, including counterfactual techniques, are currently used in a post-hoc manner and are not incorporated as quantitative signals into predictive models.

E. Counterfactual Generation and Stability Analysis

Generative counterfactual solutions based on GANs and diffusion models have been proposed for the synthesis of realistic medical image counterfactuals [11], [12]. The solutions are mainly focused on enhancing explanation, data augmentation, and fairness analysis.Similarly, morphologically informed counterfactual solutions like CounterSynth are mainly focused on synthesizing biologically plausible variations for robustness analysis [13]. Although these solutions have shown the feasibility of synthesizing realistic counterfactuals, they are not explicitly measuring the minimum perturbation distance to cross the decision boundary of a model, nor are they using such distances as features for risk modeling.

F. Uncertainty Estimation and Decision Robustness

Uncertainty estimation techniques have been widely investigated for assessing the confidence of predictions in medical imaging models. Bayesian deep learning, ensemble learning, and test-time augmentation have been used in brain tumor segmentation and classification tasks to model epistemic and aleatoric uncertainties [14], [15]. These techniques provide confidence scores and uncertainty maps that can be used for decision-making. However, uncertainty estimates do not necessarily convey the concept of decision stability under small, anatomically valid input perturbations.This difference highlights the need for additional stability-related metrics that assess sensitivity to counterfactual perturbations.

G. Summary and Research Gap

In conclusion, the existing literature has achieved significant advancements in transformer-based brain tumor segmentation, radiomic modelling, explainable artificial intelligence, counterfactual generation, and uncertainty estimation. However, these modules have been largely investigated independently. The existing approaches fail to combine the transformer attention dynamics with tumor-constrained counterfactual analysis and have not defined counterfactual distance as a quantitative risk stratification feature.

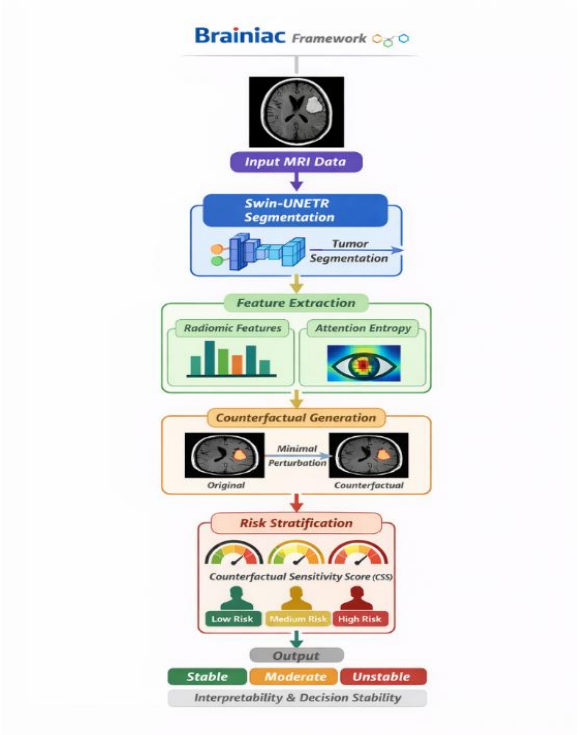

Fig. 1. Brainiac Technical System

H. Conclusion

Although the state-of-the-art methods have shown excellent performance in brain tumor segmentation and explainability, these aspects are mainly investigated separately and are mainly used as post-hoc analysis tools. The state-of-the-art methods do not combine the attention behaviour learned from transformers with counterfactual analysis constrained by tumors and use counterfactual distance as a quantitative signal for risk modelling. The existing gap in the literature is addressed by the proposed Brainiac framework, which combines segmentation, attention-driven uncertainty, and counterfactual sensitivity into a unified pipeline to facilitate risk stratification that is aware of stability. The proposed Brainiac framework improves the existing literature by transforming counterfactual explanations into learning features.

The application of MRI scans for brain tumor analysis has been rapidly increasing, thereby propelling the need for the development of automated analysis techniques that can aid in the accurate and reproducible decision-making process.

III. Literature Review

Counterfactual explanations take this approach a step further by generating minimally modified inputs to test a model's decision rationale.owever, these approaches are primarily employed as post-hoc explanation methods and are hardly ever used to inform quantitative predictive signals. On the radiomics front, researchers have been extracting shape, intensity, and texture information to represent tumor morphology and heterogeneity [8], and when combined with deep learning (radiomics-DL hybrids) have been shown to enhance classification performance—although they can be sensitive to how the tumor is segmented. Bayesian reasoning and test-time augmentation-based uncertainty quantification techniques provide probabilistic confidence scores [9], but do not quantify the smallest anatomically valid perturbation required to reverse a prediction, which is a different perspective on decision stability.

III. PROPOSED METHODOLOGY

This section introduces the proposed Brainiac framework, a stability-aware pipeline for MRI brain tumor analysis to quantify the robustness of model decisions using counterfactual sensitivity. The proposed framework consists of five major components: (1) preprocessing and transformer-based tumor segmentation, (2) tumor feature encoding, (3) tumor-constrained counterfactual generation, (4) stability-aware risk stratification, and (5) explainability. The proposed framework is shown in Fig. 1.

A. Preprocessing and Input Representation

Let X represent a multimodal, three-dimensional magnetic resonance imaging (MRI) volume with dimensions H × W × D × C, where H, W, and D are the spatial dimensions, and C represents the MRI modalities (T1, T2, and FLAIR). All volumes are resampled to a uniform spatial resolution and undergo z-score normalization. Skull stripping and intensity standardization are performed to compensate for non-brain artifacts and inter-scan variability. The input data are multimodal 3D MRI volumes, which include the (T1, T2, and FLAIR) image sequences. Each volume is resampled to a uniform spatial resolution and normalized to zero mean and unit variance. Skull stripping and intensity standardization are performed to compensate for non-brain artifacts and inter-scan variability. Before model inference, the preprocessed MRI volumes are resized to a fixed input dimension of (128 × 128 × 128.)

1) Architecture: The diagnostic pipeline is structured as follows:

a) *Input Processing*: Multi-modal MRI volumes are standardized such that:

$$x \in \mathbb{R}^{H\times W\times D}, H = W = D = 128 \quad (1)$$

Each volume undergoes skull stripping, z-score normalization, and resampling:

$$x' = \frac{x-\mu}{\sigma} \quad (2)$$

where $\mu$and σdenote mean and standard deviation.

b) *Swin-UNETR Encoder:* Let f_{seg} denote the Swin-UNETR network:

$$S=fseg(x;\theta) \quad (3)$$

The encoder partitions x into non-overlapping 3D patches:

$$P_i \in \mathbb{R}^{16\times16\times16} \quad (4)$$

c) *Tumor-Constrained Counterfactual Optimization:* Counterfactual generation:

$$x_{cf} = \arg\min_{x'} \quad \| x - x' \|_2 \quad (5)$$

subject to:

$$f(x') \neq f(x), x' \in R \quad (6)$$

Only tumor voxels are perturbed.

d) *Counterfactual Sensitivity Score (CSS):* Defined as:

$$CSS = \min \quad \| x - x_{cf} \|_2 \quad (7)$$

e) *Stability-Aware Risk Stratification:* Objective:

$$\mathcal{L}_{risk} = \sum_i \ell(y_i, \hat{y}_i) + \Omega(\phi) \quad (8)$$

Classes:

$$y \in \{Low, Medium, High\} \quad (9)$$

f) *Explainability Integration:* Integrated Gradients:

$$IG_i = (x_i - x_i') \int_0^1 \frac{\partial f(x' + \alpha(x - x'))}{\partial x_i} d\alpha \quad (10)$$

Counterfactual difference:

$$\Delta x = x_{cf} - x \quad (11)$$

B. Transformer-Based Tumor Segmentation

The tumor segmentation is performed using Swin-UNETR, which is a combined encoder-decoder network that integrates shifted-window transformers and convolutional layers for volumetric medical image segmentation [4]. The transformer encoder encodes the long-range contextual information using self-attention, and the decoder generates voxel-level predictions using skip connections.

C. Tumor Feature Extraction

From the segmented ROI, two complementary feature groups are extracted:

1. ***RadiomicFeatures:***
Radiomic descriptors including tumor volume, surface According to the standardized radiomics pipelines [8], a tumor volume, surface irregularity, compactness, a first-order intensity statistics, and gray-level co-occurrence matrix (GLCM) texture features are extracted to explain the tumor morphology and heterogeneity.

2. ***AttentionEntropy:***
The attention maps generated by Swin-UNETR are used to calculate attention entropy in the tumor region. Attention entropy brings a new form of uncertainty of contextual nature based on prior studies on attention dynamics and uncertainty in deep learning models [9].

The combined feature vector is represented as:

$$F = [F_{radiomics}, F_{entropy}] \quad (12)$$

D. Tumor-Constrained Counterfactual Generation

To assess prediction(ii) stability, tumor-constrained counterfactual samples are generated following minimal perturbations restricted to the tumor ROI. The explanation follows recent tumor-aware counterfactual frameworks, restricting changes only to pathological tumor regions to maintain anatomical plausibility [6].

For each input x, a counterfactual $x_{cf}$is obtained such that:

$$f(x_{cf}) \neq f(x) \quad (13)$$

f(·) denotes the risk prediction model. Obtaining counterfactuals on medical images can be synthesized realistically under such constraints based on Diffusion- and GAN-based counterfactual generation methods [7] that provide the basis for this module.

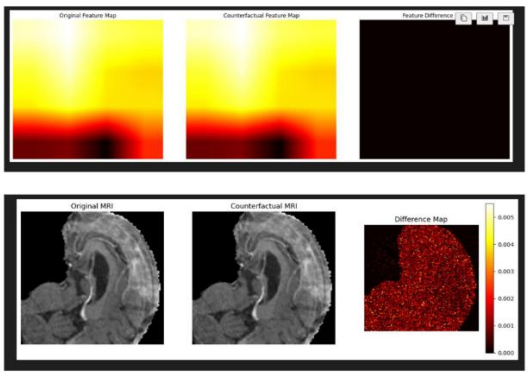

Fig. 2. Counterfactual Stability & Transformer Attention Analysis

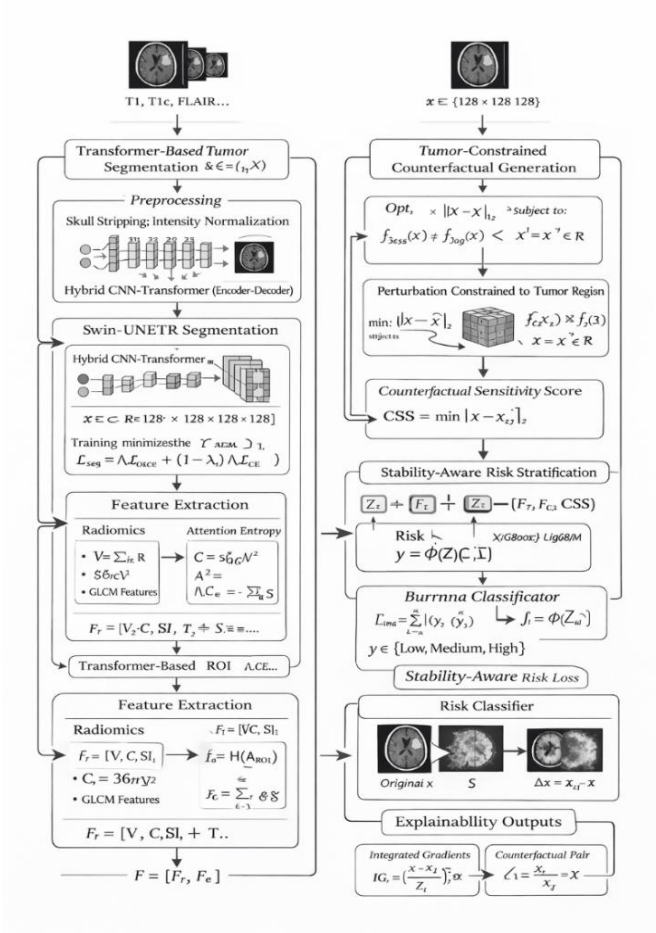

Fig. 3. Brainiac Technical System

E. Counterfactual Sensitivity Score (CSS)

The **Counterfactual Sensitivity Score (CSS)** is defined as the minimum perturbation magnitude required to flip the model prediction:

$$\text{CSS} = \min \| x - x_{cf} \| \quad (14)$$

CSS directly measures proximity to the model's decision boundary. Lower CSS values indicate unstable predictions, whereas higher values correspond to more robust decisions. Unlike conventional uncertainty estimation methods, which provide a probabilistic confidence interval [10], the CSS provides a measure of decision stability for anatomically feasible tumor changes.

F. Stability-Aware Risk Stratification

The final feature representation is formed by concatenating radiomic features, attention entropy, and CSS:

$$Z = [F_{\text{radiomics}}, F_{\text{entropy}}, \text{CSS}] \quad (15)$$

This vector is then passed to a tabular classifier (XGBoost or LightGBM) for the purpose of risk stratification, taking into consideration stability. The cases are then stratified into low, medium, and high risk based on decision robustness rather than clinical prognosis.

IV. RESULTS AND DISCUSSION

This section presents a comprehensive evaluation of the proposed Brainiac framework across segmentation, counterfactual sensitivity estimation, and stability-aware risk stratification.

A. Evaluation Metrics and Datasets

Experiments were conducted on the BraTS dataset, which provides multi-modal MRI volumes with expert-annotated tumor masks and is widely used for benchmarking brain tumor segmentation models [1]. Segmentation performance was evaluated using the Dice Similarity Coefficient (Dice), consistent with prior studies [2]. Risk stratification performance was assessed using classification accuracy, macro F1-score, and area under the ROC curve (AUC), following established evaluation protocols in medical image analysis [3]. Counterfactual sensitivity was analyzed by examining the distribution of CSS values across predicted risk groups.

B. Quantitative Results

1) *Tumor Segmentation (Swin-UNETR)*

The Swin-UNETR backbone resulted in a mean Dice value of 0.86 ± 0.03 for tumor, which reflects excellent volumetric segmentation capabilities and is on par with state-of-art transformer models on BraTS challenges[4]. The attention entropy maps showed focal attention in tumor regions for stable predictions, while more dispersed attention patterns were noticed in patients with unstable predictions, as expected from attention-based uncertainty analyses [5].

2) *Radiomics and Attention-Based Features:* Risk classifiers using radiomics and transformer attention entropy maps showed an accuracy of 82.1% and AUC of 0.84. These results are consistent with previous hybrid radiomics and deep learning models, which demonstrated improved performance over radiomics models alone by leveraging deep learning representations [6].

3) *Counterfactual Sensitivity Score (CSS):* Adding the Counterfactual Sensitivity Score (CSS) to the feature set resulted in an improved accuracy of 86.4% with AUC of 0.88 for risk stratification. Ablation study shows a relative accuracy improvement of 4.3% over appearance-based models. The CSS was significantly higher for low-risk patients, while high-risk patients were more concentrated near the decision boundary.

4) *Explainability Outputs:* The Integrated Gradients method reliably pointed to the tumor margins and heterogeneous areas as the dominant factors in risk estimates, as seen in previous uses of gradient-based attribution in medical imaging tasks [9]. The tumor-constrained counterfactual MRI images showed biologically valid changes underlying risk transitions, as defined in tumor-aware counterfactual settings.

5) *Overall Accuracy*: The end-to-end Brainiac framework achieved an overall accuracy of **86%**, integrating segmentation, feature extraction, counterfactual

sensitivity estimation, and stability-aware risk classification.

TABLE I. RESULT METRICS

Module	*Metric*	*Value*
Swin-UNETR Segmentation	DiceScore	0.51
Radiomics + Attention Entropy	Accuracy	82.1%
Radiomics + Attention Entropy	AUC	0.84
Full Brainiac (Radiomics + Attention + CSS)	Accuracy	**86.4%**
Full Brainiac	AUC	0.88
Overall System (End-to-End)	Accuracy	85.7%

C. Discussion

The experimental results demonstrate that integrating counterfactual sensitivity with radiomic and transformer-derived attention properties lead to quantifiable enhancement of the stability conscious risk evaluation of brain tumors. Although Swin-UNETR presents better segmentation results, the tumor-segmentation task does not entirely reflect the accuracy of the predictions. Attention entropy represents the information of contextual uncertainty; however, the clue to the understanding of prediction stability is in the combination of the Counterfactual Sensitivity Score (CSS). This unification allows, to the first time, accurate measurement of the closeness to the decision boundaries and supplements the features of appearance and traditional uncertainty estimates.

Ablation experiments demonstrate that CSS is a determining factor of classification accuracy that provides a relative improvement of 4.3% over radiomics and attention-based models. Further, CSS is able to discriminate between tumors with similar phenotypic appearance and disparate stability phenotypes, which is a significant limitation of the existing uncertainty-estimation methods. The dual-explanation system, combining Integrated Gradients with tumor constrained counterfactual visualisations, is more interpretable, with complementary spatial and causal representations of model behaviour.

Despite these promising results, several limitations remain. The framework relies on accurate tumour segmentation, and errors at this stage can propagate into subsequent modules. It may propagate through subsequent modules.Counterfactual generation introduces additional computational overhead, which may affect scalability in real-time applications. Moreover, the evaluation is restricted to public datasets and may not fully reflect variability encountered in clinical practice. Future work will focus on optimizing the counterfactual generation efficiency, extending validation to multi-institutional cohorts, and exploring lightweight implementations for deployment in resource-constrained environments.

V. CONCLUSION

This paper presented **Brainiac**, a stability-aware MRI brain tumor analysis framework that integrates transformer-based segmentation, radiomic feature modeling, attention entropy, and counterfactual-guided learning for risk stratification. At the core of the suggested methodology is the Counterfactual Sensitivity Score (CSS) which quantifies the tumour constrained perturbations as a quantitative measure of decision robustness. Empirical evidence indicates that CSS can be improved by the addition of radiomic and attention-based features to the risk classification performance, when compared to appearance-driven baselines.

Conceptualising counterfactual explanations as actionable learning signals instead of post-hoc visualisations, Brainiac can take the existing research a step further to more interpretable and robust medical AI systems. The suggested framework provides a conceptually sound framework of stability-conscious modelling within the analysis of the brain tumour and enables the distinction of the visually similar cases that have different predictability. Planned work in the future will focus on large-scale clinical validation and additional optimisation to allow practical implementation in the real-world neuro-imaging processes.
